ABSTRACT

The combined Canada/US yellowtail flounder (*Limanda ferruginea*) catch decreased from 2005 (4,088 mt) to 2006 (2,206 mt) due mainly to a decrease in quota. Spawning stock biomass has leveled off recently, but is currently low at about 5,000 mt, indicating that stock rebuilding is needed. There are indications of a relatively strong 2005 year-class, appearing as 1 year olds in the 2006 NEFSC Fall, Spring, and Scallop surveys and as 2 year olds in the 2007 DFO and NEFSC Spring surveys. The 2005 year-class is estimated to be 63 million age-1 fish in 2006, similar to the abundance of year-classes from the 1970s. Fishing mortality rates for fully recruited ages 4+ have declined the past two years, but are still well above F_{ref} of 0.25. Truncated age structure in the surveys and contraction in distribution indicate current productivity may be limited relative to historical levels. Assuming a 2007 catch equal to the 1,250 mt quota, a combined Canada/US yield of about 3,500 mt in 2008 is expected to achieve $F_{ref} = 0.25$. However, the projected 2008 yield depends strongly on the 2005 year-class, and recent experience has shown estimates of initially strong year-classes reduced in size over time, so caution should be used when setting the 2008 quota.

RÉSUMÉ

Les prises combinées de limande à queue jaune (*Limanda ferruginea*) du Canada et des États-Unis ont diminué de 2005 à 2006, passant de 4 088 tm à 2 206 tm, principalement en raison d'une baisse du quota. La biomasse du stock de reproducteurs a récemment plafonné, mais elle est actuellement faible (environ 5 000 tm), ce qui indique que le stock doit se rétablir davantage. Il y a des indications que la classe de 2005 est relativement abondante, ce qui s'observe par le nombre de poissons d'âge 1 dans les relevés du NEFSC sur le pétoncle effectués à l'automne et au printemps de 2006, et par le nombre de poissons d'âge 2 dans les relevés du MPO et du NEFSC effectués au printemps de 2007. On estime que la classe de 2005 sera de 63 millions de poissons d'âge 1 en 2006, ce qui est semblable à l'abondance des classes de 1970. La mortalité par pêche parmi les âges pleinement recrutés (4+) a décliné au cours des deux dernières années, mais est encore de beaucoup supérieure au niveau de référence de 0,25. La structure d'âges tronquée dans les relevés et la contraction de la distribution indiquent que la productivité actuelle est peut-être limitée par rapport à ses niveaux historiques. En supposant que les prises de 2007 soient égales au quota de 1 250 tm, on s'attend à ce que le rendement combiné du Canada et des États-Unis d'environ 3 500 tm en 2008 atteigne le niveau de référence de 0,25. Toutefois, le rendement projeté de 2008 dépend en grande partie de la classe de 2005, et de récentes expériences ont montré que les estimations de la taille des classes initialement très abondantes ont diminué au fil du temps; il faudrait donc faire preuve de prudence lorsqu'on établira les quotas de 2008.

INTRODUCTION

The Georges Bank yellowtail flounder (*Limanda ferruginea*) stock is a transboundary resource in Canadian and US jurisdictions. This paper updates the last stock assessment of yellowtail flounder on Georges Bank, completed by Canada and the US (Legault et al. 2006) addressing technical recommendations from the 2005 benchmark review (TRAC 2005). A primary objective of the benchmark review was to address the retrospective pattern that had been apparent from assessments conducted during the past several years. During the benchmark assessment meeting, several analytical models were reviewed, all of which indicated poor correspondence between the catch at age and survey abundance at age that can not be reconciled. Various possible reasons for the retrospective pattern were identified including an increase in natural mortality, large amounts of unreported catch, and changes in survey catchability since 1995. The consensus view from the benchmark meeting was that management advice should be formulated on the basis of results from several approaches:

- Analysis of data from survey and fishery (trends in relative F and Z)
- 'Base Case VPA' model formulation from the 2004 assessment
- Two new VPA model formulations with minor & major changes to Base Case

The analytical methods used in the current assessment are based on revised model formulations adopted during the 2005 TRAC benchmark review using updated information from both countries on catches and survey indices of abundance.

Last year, the 'Major Change VPA' model used to provide catch advice indicated that fishing mortality had never been as low as the target rate since 1973 and had increased to high levels (>1) in 2004 and 2005 and that stock rebuilding was needed. The Base Case VPA model was rejected as the basis for management advice because trends in age 3+ biomass did not display a decline in recent years as indicated by all three surveys. Projections from the Major Change VPA model indicated that catching the TAC of 3,000 mt in 2006 would result in a fishing mortality rate above $F_{ref} = 0.25$ ($F_{2006} = 0.83$). Based on these projections, the catch quota for 2007 was set by the TMGC at 1,250 mt.

Yellowtail flounder range from southern Labrador to Chesapeake Bay and are typically caught at depths between 30 and 70 m. A major concentration occurs on Georges Bank from the northeast peak to the Great South Channel. Yellowtail flounder have previously been described as relatively sedentary, although a growing body of evidence counters this classification with off bottom movements (Walsh and Morgan 2004; Cadrin and Westwood 2004), limited seasonal movements (Royce et al. 1959; Lux 1963; Stone and Nelson 2003), and transboundary movements both east and west across the Hague Line (Stone and Nelson 2003; Cadrin 2005). On Georges Bank, spawning occurs during late spring and summer, peaking in May. Eggs are deposited on or near the bottom and after fertilization float to the surface where they drift during development. Larvae are pelagic for a month or more, then become demersal and settle to benthic habitats. Based on the distribution of both ichthyoplankton and mature adults, spawning occurs on both sides of the Hague Line. Growth is sexually dimorphic, with females growing at a faster rate than males (Lux and Nichy 1969; Moseley 1986; Cadrin 2003). Yellowtail flounder have variable maturity schedules, with age two females 40% mature during periods of high stock

biomass to 90% mature during periods of low stock biomass based on analysis of NEFSC spring survey catches.

Historical and new information pertaining to the current management unit for the Georges Bank yellowtail flounder stock was reviewed during the 2005 benchmark assessment. Tagging data, larval distribution, vital population parameters (i.e. growth, survival, recruitment, reproduction, abundance), and geographic patterns of landings and survey data indicate that Georges Bank yellowtail flounder comprise a relatively discrete stock, separate from those on the western Scotian Shelf, off Cape Cod and southern New England (Royce et al. 1959; Lux 1963; Neilson et al. 1986; Begg et al. 1999; Cadrin 2003; Stone and Nelson 2003). Based on information from a comprehensive review by Cadrin (2003) and recent results from cooperative science/industry tagging programs conducted by Canada and the US, there does not appear to be any justification for redefining the geographic boundaries of the Georges Bank yellowtail flounder stock management unit.

The management unit currently recognized by Canada and the US for the transboundary Georges Bank stock includes the entire bank east of the Great South Channel to the Northeast Peak, encompassing Canadian fisheries statistical areas 5Zj, 5Zm, 5Zn and 5Zh (Fig. 1a) and U.S. statistical reporting areas 522, 525, 551, 552, 561 and 562 (Fig. 1b). Both Canada and the US employ the same management unit. The quota sharing agreement between the two countries requires that catches from all sources be counted against the national allocations, regardless of whether the catch was landed or discarded.

THE FISHERIES

Exploitation of the Georges Bank stock began in the mid-1930s by the US trawler fleet. Landings (including discards) increased from 400 mt in 1935 to 9,800 mt in 1949, then decreased in the early 1950s to 2,000 mt in 1956, and increased again in the late 1950s (Fig. 2). The highest annual catches occurred during 1963-1976 (average: 17,500 mt) and included modest catches by foreign fleets (Table 1). No catches of yellowtail by nations other than Canada and USA have occurred since 1975. Catches averaged around 3,500 mt between 1985 and 1994, then dropped to a record low of 1,183 mt in 1995 when fishing effort was markedly reduced in order to allow the stock to rebuild. The US fishery in the management area has been constrained by spatial expansion of Closed Area II (Fig. 1b) and by extension to year-round closure in December 1994, as well as larger mesh size and gear regulations and limits on days fished. In 2004, a Yellowtail Special Access Program (SAP) in Closed Area II allowed the US bottom trawl fishery short-term access to the area for the first time since 1995. This SAP did not continue in 2005 or 2006. Catches by both nations (including discards) steadily increased (with increasing quotas) from a record low of 1,183 mt in 1995, when the stock was considered to be in a collapsed state, to 7,857 mt in 2001. Since 2004, decreasing quotas and an inability of Canadian fishermen to fill their portion of the quota have resulted in declining catches of 7,275 mt (2004), 4,088 mt (2005), and 2,206 mt (2006).

United States

The principal fishing gear used in the US fishery to catch yellowtail flounder is the otter trawl, accounting for more than 98% of the total USA landings in recent years, although scallop dredges account for some landings (<2%). US trawlers that land yellowtail flounder generally target multiple species on the southwest part of the Bank, and on the northern edge along the western and southern boundaries of Closed Area II. Current levels of recreational fishing are negligible.

In May of 2004, a new electronic dealer reporting system was implemented in the Northeast for US landings. This new reporting system did not allow the typical proration to stock area scheme using logbook data as described in Cadrin et al. (1998) because neither the area fished nor gear code was included in many of the dealer records. Gear codes were assigned to permits that had only used a single gear based on logbook records. This allowed the typical proration scheme to be used. Examination of patterns of landings reported in the dealer database and those in the logbook records show similar trends in terms of time of year, gear, and port. Thus, there is no indication of a systematic bias in these allocations. Total yellowtail landings (excluding discards) for the 2006 USA fishery were 1,239 mt, a decrease of 63% from 2005 (Table 1; Fig. 2).

Total discards of yellowtail in the US decreased approximately 20% from 2005 (476 mt) to 2006 (377 mt). This decrease was due almost entirely to a decrease in trawl discards, associated with a large decrease in trawl landings, while dredge discards remained the same. Although scallop landings from Georges Bank were high in 2005 and increased in 2006, the high densities of scallops relative to the low densities of yellowtail resulted in a similar discard estimate. In 2006, 28% of yellowtail discards originated from the trawl fishery (106 t), while the majority (72%) came from the scallop fishery (270 t). The trawl fishery estimates of discards were obtained from discard to kept (d:k) ratios of yellowtail based on observer data (Table 2). Comparison of these d:k ratios from observers and logbooks showed that logbook values were slightly lower than observer values for similar time periods, but the same pattern over time was present.

The scallop dredge fishery had two Special Access Programs (SAPs) on Georges Bank, one in Closed Area I and the other in Closed Area II, in addition to fishing in open areas. These SAPs attracted effort to Georges Bank and caused the landings of scallops to increase from 6,800 mt in 2005 to 9,200 mt in 2006. The spatial extent of the Georges Bank stock differs between the yellowtail flounder and scallop assessments, specifically, the scallop assessment includes the Great South Channel while the yellowtail flounder assessment does not. Scallop values presented in this document were calculated for the yellowtail flounder stock definition. Due to the negligible landings of yellowtail in the scallop fishery, the d:k ratio of yellowtail could not be applied. The high landings of scallops caused difficulty for the regression method used in the last benchmark assessment to estimate discards of yellowtail from landings of scallops. Specifically, the observed scallop landings in 2006 were more than double the highest values used to generate the regression. Following the approach of last year, discard of yellowtail to kept scallop ratios were computed from observer data in CAI, CAII, and open areas of Georges Bank (Table 2).

Scallop landings by area were approximated based on ratios of VTR landings by commercial statistical areas with area 522 representing CAI, statistical area 562 representing CAII, and statistical areas 525, 551, 552, and 561 representing open areas. This approximation was

necessary because landings are not attributed to sampling programs in the dealer landings database. Since the landings of scallops came mostly from CAII during the second half of 2006, the estimated d:k ratio is most important for this area and time. There were 33 observed trips in CAII during half 2, which resulted in an estimated ratio of discarded yellowtail to kept scallops of approximately 5%, which is similar to the estimate from 2005 of 6% based on 24 observed trips. Multiplying scallop landings by the d:k ratio results in yellowtail discards of 252 mt for CAII in the second half of 2006. There were nine observed trips in CAII during the first half of 2006 which produced a d:k ratio of approximately 1.5% and yellowtail discards of 8 mt. This is also similar to 2005 half 1 when four observed trips produced an estimated d:k ratio of 2%. The second half d:k ratio was 5%. The reason for the difference in discarding rate between the first and second half of 2006 in CAII is unknown, but could relate to seasonal movements of yellowtail on Georges Bank as suggested by comparison of highest densities in DFO and NEFSC spring surveys versus NEFSC fall survey (Fig. 3).

There was only a single observed trip in CAI, and it had a low d:k ratio, as seen last year for this area (0.0016 in 2005), and scallop landings from this area were low (8% of the total) resulting in yellowtail discards of <1 mt. Application of even a much higher d:k ratio to the CAI scallop landings would not substantially change the estimated discards from Georges Bank. There were nine observed trips in open areas of Georges Bank during 2006 which produced a d:k ratio of 0.4%. This ratio is much lower than that observed in CAII, but could be due to the low densities of yellowtail flounder outside of CAII. Multiplying the d:k ratio by the scallop landings from open areas (31% of the total) produces yellowtail discards of 9.9 mt.

This approach differs from last year's assessment when insufficient observer data was available for open areas and so the regression approach was applied. Applying the regression approach this year would result in 292 mt of yellowtail discards and an implied d:k ratio of 10%. However, this was not done this year because the nine observed trips were assumed to be representative of the scallop fishery in open areas during 2006 and the regression approach is based on data from 1994 to 2000 when both scallop and yellowtail densities were much different. Estimation of yellowtail discards in the scallop dredge fishery continues to be a source of uncertainty in the Georges Bank yellowtail flounder assessment.

The total US catch of Georges Bank yellowtail flounder in 2006, including discards, was 1,616 mt. The US Georges Bank yellowtail flounder quota for fishing year 2006 (1 May 2006 to 30 April 2007) was set at 2,070 mt. Monitoring of the US catches relative to the quota was based on Vessel Monitoring Systems (VMS) and a call-in system for both landings and discards. The assessment methodology and the monitoring methodology to estimate landings and discards were compared for the calendar year 2006. The monitoring system estimated catch to be approximately 1700 mt (5% higher than the assessment catch). This match is the same as the second half of 2005 when the monitoring methodology was 6% higher than the assessment methodology.

Canada

Canadian fishermen initiated a directed fishery for yellowtail flounder on Georges Bank in 1993. Prior to 1993, Canadian landings were low, typically less than 60 mt (Table 1, Fig. 2). Landings of 2,139 mt of yellowtail occurred in 1994, when the fishery was unrestricted. After a TAC of

400 mt was established, yellowtail landings dropped to 464 mt in 1995. Subsequently, both quotas and landings increased and in 2001 were 2,913 mt. The majority of Canadian landings of yellowtail flounder are made by otter trawl from vessels less than 20 m, tonnage classes 1-3. The Canadian fishery generally occurs from June to December, with most landings in the third quarter. In 2004, landings were 96 mt (against a quota of 1,900 mt). Unlike other years, Canadian fishermen were unable to find commercial quantities of yellowtail in 2004 and the directed fishery ceased in September. In 2005, landings were 30 mt (against a quota of 1,740 mt) and in 2006 landings were 25 mt (against a quota of 930 mt), because Canadian fishermen were still unable to find commercial quantities of yellowtail (Table 1). Most of the yellowtail landings reported for 2006 were from trips directed for other groundfish species (i.e. cod, haddock). Flatfish landed as "unspecified" in the Canadian fishery are also included in the total Canadian landings and were estimated at 5.3 mt for 2006, following methods used in previous assessments. This amount was added to the reported yellowtail landings of 19.5 mt, bringing the total up to 25 mt for 2006.

The Canadian offshore scallop fishery is the source of Canadian yellowtail flounder discards on Georges Bank. As a result of the 2005 benchmark review, these data are now incorporated into the Canadian fishery catch and catch at age for 1973 onward. Prior to 1996, landing of groundfish bycatch by the Canadian scallop fishery on Georges Bank was allowed; however, not all the yellowtail flounder bycatch was landed. To account for the total bycatch for 1973-1995, it was necessary to augment the yellowtail landings by the yellowtail discarded in the scallop fishery. Management measures established in 1996 prohibit the landing of groundfish (except monkfish) by the Canadian scallop fishery, and all bycatch of yellowtail flounder is now discarded. Discards, whether pre or post 1996, are not recorded in the Canadian fishery statistics and can only be estimated from observer deployments.

Prior to 2001, very few Canadian scallop trips on Georges Bank had at-sea observer coverage; only nine trips were monitored from 1991 to 1998. In response to a Fisheries Resource Conservation Council recommendation, a monitoring program of the Canadian offshore scallop industry was conducted in 2001 and 2002 to gather data on bycatches. Twelve trips were observed which covered all months except January and October. In August 2004, routine observer coverage was initiated on vessels in the Canadian scallop fishery on Georges Bank. A total of 5 trips were observed in 2004, 11 in 2005, and 11 in 2006.

Van Eeckhaute et al. (2005) provide the methodology used for estimating yellowtail flounder discards in the Canadian scallop fishery during 1960-2004 based on observer data (although only estimates for catches since 1973 are used in the stock assessment). For 1996-2004, when yellowtail flounder landings were not permitted, effort in the scallop fishery was prorated by the observed discard rate of yellowtail to effort to obtain an estimate of discards. While the available data do not support any spatial trends in discard rates, higher discard rates occur in April, May and June than in November and December. Therefore, the proration was conducted using discard rate by quarter. Quarterly discard rates for periods when no observed trips were available were derived by interpolation and application of a seasonal pattern. To estimate discards for year 1996 and later, the quarterly discard rates were applied to the total quarterly effort of the scallop fleet. The seasonal pattern in bycatch rate for years 2005 and 2006 is taken into account by applying calculations using 3-month moving windows. In the past, separate estimates for each quarter

were calculated and then added together. This new approach has been used to update the 2005 estimate of yellowtail discards in the Canadian scallop dredge fishery from 317 mt to 255 mt. Application of this approach to data in 2006 results in a discard estimate of 565 mt (Table 2). The estimate of discards in 2006 is heavily influenced by a single observed trip which had a high discard rate of yellowtail flounder. Excluding this trip from the calculations produced an estimate of 210 mt. However, there were no reasons other than the high discard rate of yellowtail to exclude this trip from the calculations, so the discards of yellowtail in the Canadian scallop fishery for 2006 are 565 mt.

For 1973-1995, the number of observed trips was very limited and the ratios were subject to influence by anomalous outliers. An effort-based proration was used without seasonal factors because that refinement was not considered warranted given the limitations of the available information for this period. The approach used for both periods is dependent on the assumption that the bycatch population density, i.e. the *discard+landed yellowtail / scallop effort* ratio for observed scallop fishing is representative of that for the scallop fishery as well as on the assumption that discarding practices are representative. Estimation of yellowtail discards in the scallop dredge fishery continues to be a source of uncertainty in the Georges Bank yellowtail flounder assessment.

Discard estimates from 1973-2006 averaged 538 mt and ranged from a low of 255 mt in 2005 to a high of 815 mt in 2001 (Table 1). For 2006, the total Canadian catch, including discards, was 590 mt, an increase of 107% from 2005 but well below the 2006 TAC of 930 mt.

Length and Age Composition

In 2006, 880 length measurements were available from 4 port samples from the Canadian fishery (Table 3) and were used to estimate the Canadian catch at size, by sex and quarter. No length measurements were utilized from at sea observer deployments because sex determinations from these samples were found to be inaccurate.

The US landings are classified by market category (large, small, and unclassified) and this categorization is used to determine the size and age distributions. The number of US port samples increased in 2006, with 9,320 length measurements available from 95 samples, even though US yellowtail landings declined by about 60% from 2005 (Tables 1 and 3). This compares with 8,295 measurements from 81 samples in 2005. The 95 port samples also provided 2,125 age measurements for use in age-length keys. At-sea sampling decreased slightly in 2006 and provided an additional 34,073 length measurements, which were combined with the port samples to characterize the size composition of the 'unclassified' market category of US catch.

Both the amount and the proportion of yellowtail landed in the large market category have generally increased since 1995 (from approximately 50% to approximately 75%) although the 2006 proportion was 67%. Examination of the size distributions of the two market categories continues to show some overlap in the 35-38 cm range, but overall discrimination between the groups (Fig. 4). The proportion of the landings in the large market category that are 45 cm and larger increased during 2000 through 2004; 5%, 8%, 12%, 22%, 20%, respectively, but then declined to 7% in 2005 and 12% in 2006.

The size composition of yellowtail flounder discards in the Canadian offshore scallop fishery was estimated by half year using length measurements obtained from 11 observed trips in 2006. These were prorated to the total estimated bycatch at size using the corresponding half year length-weight relationship and the estimated half year bycatch (mt), calculated using the methods of Stone and Gavaris (2005). Discards at age by half year were then obtained using half year age-length keys based on the following combined ages: Half 1 US commercial fishery + NMFS spring survey + DFO survey, and Half 2 US commercial fishery + NMFS fall survey. Yellowtail discards from the Canadian scallop fishery were generally larger during the first half year (Fig. 5) indicating a higher catchability of larger fish which is likely related to their gravid condition and peak spawning during April through June.

US discard length frequencies were generated from observer data, expanded to the total weight of discards by gear type and half year. Trawl discards were mostly due to minimum size culling (Fig. 6). Dredge discards were low in the first six months of 2006 and similar in size distribution to the second half discards, in that most discards were mainly legal sized fish which is consistent with previous observations (Fig. 6).

A comparison of the size composition of yellowtail catch by country revealed that the Canadian landings were slightly smaller in size than US landings (Fig. 7a) while Canadian discards were slightly larger in size than US discards (Fig. 7b). The relative magnitude of landings and discards by each country resulted in total catch for Canada having slightly smaller average size than the total catch for the US (Fig. 8).

Although otoliths are used to determine ages for Grand Bank yellowtail (Walsh and Burnett 2001), age determination of Georges Bank yellowtail flounder using otoliths is hampered by the presence of weak, diffuse or split opaque zones and strong checks, which can make interpretation of annuli subjective and difficult (Stone and Perley 2002). Therefore, scales are the preferred structure for aging Georges Bank yellowtail flounder. Percent agreement on scale ages by the US readers continues to be high (>85% for most studies) with no indication of bias (J. Burnett, NMFS, TRAC Working Paper, 2007).

No scale samples were available for the Canadian fishery in 2006. Therefore, age samples from US port sampling, the NMFS spring and fall surveys and the DFO survey were used to construct the catch at age by sex by half year for the 2006 Canadian landings.

For the US fishery, sample length frequencies were expanded to total landings at size using the ratio of landings to sample weight (predicted from length-weight relationships by season; Lux 1969), and apportioned to age using pooled-sex age-length keys in half year groups. Landings were converted by market category and half-year, while discards were converted by gear and half-year.

In 2006, ages 2, 3, and 4 (2004, 2003, and 2002 year classes, respectively) dominated both Canadian and US landings, with age 3 predominant (Fig. 9). Since the mid 1990s, ages 2-4 have constituted most of the exploited population, with very low catches of age 1 fish due to the implementation of larger mesh in the cod end of commercial trawl gear (Table 4; Fig. 10).

The fishery mean weights at age for each of the Canadian and US landings and discards were derived using the age-length keys, and applicable length frequencies, and length-weight relationships. The mean weight at age (kg) for the Canadian and US landings were quite similar and generally were more variable at older ages (5+) during the mid 1980s to the mid 1990s. The overall fishery weights at age were calculated from Canadian and US landings and discards, weighting by the respective catch at age (Table 5; Fig. 11). A trend of increasing weight at age is apparent in both fisheries for all ages since 1995, returning to levels seen in the late 1970s/early 1980s. Recent weight at age (WAA) values are within the range of past WAA calculations since 1973.

ABUNDANCE INDICES

Research Vessel Surveys

Bottom trawl surveys are conducted annually on Georges Bank by DFO in the spring (February) and by the US National Marine Fisheries Service (NMFS) in the spring (April) and fall (October). Both agencies use a stratified random design, though different strata boundaries are defined for each survey (Fig. 12). NMFS spring and fall bottom trawl survey catches (strata 13-21), NMFS scallop survey catches (scallop strata 54, 55, 58-72, 74), and DFO spring bottom trawl survey catches (strata 5Z1-5Z4) were used to estimate relative stock biomass and relative abundance at age for Georges Bank yellowtail. Conversion coefficients, which adjust for survey door, vessel, and net changes in NMFS groundfish surveys (1.22 for old doors, 0.85 for the Delaware II, and 1.76 for the Yankee 41 net; Rago et al. 1994) were applied to the catch of each tow.

Yellowtail flounder biomass indices from the three groundfish surveys correspond with each other reasonably well over the past two decades. DFO survey biomass indices increased from 1995 to 2001 (the highest value in the series), declined through 2004 and fluctuated since (Table 6; Fig. 13). The current index is still higher than any observed during the mid-1990s when the stock had collapsed. The NMFS spring series tracks the DFO series well during the years of overlap up to 1999, then shows a decline through to 2001 followed by a sharp increase in 2002 (Table 7; Fig. 13). Similar to the DFO series, the NMFS spring biomass index sharply declined from 2002 to 2004 (the lowest value since 1994) and has generally increased since. The NMFS fall survey, which is the longest running time series, also increased from 1995 to 1999, fell slightly in 2000 followed by a large increase in 2001 (Table 8; Fig. 13). The NMFS fall index showed a strong decline between 2001 and 2002, and has fluctuated since. The NMFS fall index is at a relatively high level compared to the mid 1990's when the stock was collapsed. Both the NMFS spring and fall survey indices show high inter-annual variability during the periods of high abundance (i.e. the 1960s and 1970s) which may reflect the patchy distribution of yellowtail on Georges Bank and the low sampling density of NMFS surveys.

The distribution of catches (weight/tow) for the most recent year is compared with the previous five year average for all three surveys in Fig. 3. Since 1996, most of the DFO survey biomass and abundance of yellowtail flounder has occurred in Stratum 5Z4, which includes the lower portion of Closed Area II on the US side, where no commercial groundfish fishing was allowed from December 1994 through 2003 (Fig. 14). Survey indices for this stratum tend to be quite

variable due to low sampling intensity, but show a higher level since 1996 relative to pre 1995. Stratum 5Z2 (CDN portion of Georges < 90 m depth) has also shown an increasing trend in biomass and abundance since 1996, but at a lower level than 5Z4. Both the 2005 and 2006 surveys indicate that both biomass and abundance declined within strata 5Z2, despite the fact that there was only a limited Canadian fishery in 2004 and 2005, the 2007 values have increased to approximately half the values seen from 1999 through 2004.

The two NMFS surveys cover a longer time period than the DFO survey and show a greater change in spatial distribution of yellowtail on Georges Bank. Both the NMFS Spring and Fall surveys show a large increase in the importance of stratum 16 over time (Fig. 15). When the DFO survey data is converted to the NEFSC strata using domain estimation (Särndal et al. 1992; see appendix), a similar increasing trend in the importance of stratum 16 over time is also observed (Fig. 15). Stratum 16 contains the lower portion of Closed Area II as well as the "Yellowtail Hole" in Canadian waters. Early in the time series, strata 13 and 19 both contributed substantially to the overall Georges Bank indices for both seasons, but in recent years stratum 16 has accounted for approximately 90% of the survey index in all three series (Fig. 15). The increase in importance of stratum 16 could be due to an increase in density within Closed Area II, a decrease in density in the other strata, or, more likely, both. This indicates that the resource has become much more spatially concentrated on Georges Bank. Given that recent tagging studies have shown that yellowtail move throughout Georges Bank much more than previously thought (Tallack et al. 2005; see also www.cooperative-tagging.org website), changes in density by strata could also be due to a change in behavior over time.

Age-structured indices of abundance for NMFS spring and fall surveys were derived using survey-specific age-length keys. In the past, age-length keys from NMFS spring surveys have been substituted to derive age composition for same-year DFO spring surveys, as no ages were available from the DFO surveys because of difficulties associated with age interpretation from otoliths (Stone and Perley 2002). To avoid having to use substituted age data, NMFS personnel are now ageing scales collected on DFO surveys. From the 2007 DFO survey, 342 male and 234 female fish were aged and used to produce separate-sex age-length keys, subsequently used to generate the 2007 DFO age-specific indices of abundance.

All three bottom trawl surveys along with the NMFS scallop survey indicate the possibility of a strong 2005 year-class (Tables 6-9; Figs. 16-17). The NMFS fall 2006 age 1 index is the highest value since 1969 and the NMFS scallop 2006 age 1 index is the highest in the time series, which began in 1982. The NMFS spring 2007 age 2 index is the highest value since 1972 and DFO 2007 age 2 index is the highest value since 2001. The age 1 yellowtail flounder in 2006 would have been too small to be highly selected by the NMFS spring or DFO surveys. Even though all four surveys appear to indicate a strong 2005 year-class, overall, survey age-structured indices do not track cohorts well and there are some indications of year-effects within the time series.

Trends in relative fishing mortality and total mortality from the surveys were examined as part of the consensus benchmark formulations agreed to at the second benchmark assessment meeting in April 2005. Relative fishing mortality (fishery biomass/survey biomass, scaled to the mean for 1987-2005) was quite variable but followed a similar trend for all three surveys, with a sharp decline to low levels in 1995 and a marked increase in 2004 (Fig. 18). In contrast, estimates of

total mortality rates from the surveys for ages 2, 3 and 4-6, although noisy, are without trend and indicate no reduction in mortality over time (Fig. 19).

ESTIMATION OF STOCK PARAMETERS

Results from assessment analyses conducted in recent years have displayed: a) retrospective patterns; b) residual patterns that are indicative of a discontinuity starting in 1995; and c) terminal fishing mortality rates (i.e., those associated with the last year of catch in the assessment) that are not consistent with the decline in abundance along cohorts evident in the survey data. Essentially, the catch at age data and assumed natural mortality rate cannot be reconciled with the high survey abundance indices at ages 2 and 3 and low survey abundance at ages 4 and older.

The empirical evidence suggests that significant modifications to assumed population and fishery dynamics are required to reconcile the fishery and the survey observations. Models that adopt such modifications imply major consequences in underlying processes or fishery monitoring procedures. The magnitude of implied changes to natural mortality rate, survey catchability relationships, or unreported catch is beyond realistic expectations.

In view of these reservations, adoption of a benchmark formulation that incorporated these modifications to assumptions, as the sole basis for management advice was not advocated (TRAC 2005). Therefore the TRAC recommended that management advice be formulated after considering the results from two VPA approaches described below. The 'Minor Change VPA' developed for the 2005 benchmark assessment was not accepted for subsequent update assessments due to changes in partial recruitment and associated problems in the fitting the model to observed data. The Minor Change VPA was not considered in this assessment.

The VPAs are calibrated using the adaptive framework, ADAPT, (Gavaris 1988) to calibrate the sequential population analysis with the research survey abundance trend results, specifically the NOAA Fisheries Toolbox VPA v2.7. The model formulation employed assumed error in the catch at age was negligible. Errors in the abundance indices were assumed independent and identically distributed after taking natural logarithms of the values. Zero observations for abundance indices were treated as missing data, because the logarithm of zero is undefined. The annual natural mortality rate, M , was assumed constant and equal to 0.2 for all ages. The fishing mortality rates for age groups 5 and 6+ were assumed equal. These model assumptions and methods were the same as those applied in the last assessment (Legault et al. 2006). Both point estimates and bootstrap statistics of the estimated parameters were derived using only the US software for this assessment.

1. Base Case VPA

The Base Case Virtual Population Analysis (VPA) used revised annual catch at age (including US and Canadian discards), $C_{a,t}$ for ages $a = 1$ to 6+, and time $t = 1973$ to 2006, where t represents the beginning of the time interval during which the catch was taken. The VPA was calibrated to bottom trawl and scallop survey abundance indices, $I_{s,a,t}$ for:

s_1 = DFO spring, ages $a = 2$ to $6+$, time $t = 1987$ to 2007
 s_2 = NMFS spring (Yankee 41), ages $a = 1$ to $6+$, time $t = 1973$ to 1981
 s_3 = NMFS spring (Yankee 36), ages $a = 1$ to $6+$, time $t = 1982$ to 2007
 s_4 = NMFS fall, ages $a = 1$ to $6+$, time $t = 1973.5$ to 2006.5
 s_5 = NMFS scallop, age $a = 1$, time $t = 1982.5$ to 2006.5

Data were aggregated for ages 6 and older to mitigate against frequent zero observations at older ages. This is the same formulation used since 1996.

2. Major Change VPA

The Major Change VPA recommended during the benchmark assessment expanded the ages from $6+$ to 12 , assumed a constant small number of fish (1000) survived to the start of age 13 , allowed power relationships between indices and population abundance for younger ages ($1-3$), and split the survey time series at 1995. This model could not be fit well last year or this year due to a lack of catch at old ages creating bimodal bootstrap distributions. Following the procedure of last year, the Major Change VPA was the same as the Base Case VPA with the exception that the survey time series were split at 1995. This one difference was sufficient last year to remove the retrospective pattern and pattern in residuals, and was recommended for management advice because it more closely followed the pattern observed in the indices. This formulation was used again this year as the Major Change VPA. The VPA was calibrated to bottom trawl survey indices, $I_{s,a,t}$, for:

s_1 = DFO spring, ages $a = 2$ to $6+$, time $t = 1987$ to 1994
 s_2 = DFO spring, ages $a = 2$ to $6+$, time $t = 1995$ to 2007
 s_3 = NMFS spring (Yankee 41), ages $a = 1$ to $6+$, time $t = 1973$ to 1981
 s_4 = NMFS spring (Yankee 36), ages $a = 1$ to $6+$, time $t = 1982$ to 1994
 s_5 = NMFS spring (Yankee 36), ages $a = 1$ to $6+$, time $t = 1995$ to 2007
 s_6 = NMFS fall, ages $a = 1$ to $6+$, time $t = 1973.5$ to 1994.5
 s_7 = NMFS fall, ages $a = 1$ to $6+$, time $t = 1995.5$ to 2006.5
 s_8 = NMFS scallop, ages $a = 1$, time $t = 1982.5$ to 1994.5
 s_9 = NMFS scallop, ages $a = 1$, time $t = 1995.5$ to 2006.5

Splitting the survey time series at 1995 could not be justified based on changes in the survey design or implementation. Rather the split is considered to alias unknown mechanisms causing the retrospective pattern in the Base Case VPA. Relationships between indices and population abundance for all ages were assumed to be proportional. Population abundance at age 1 in the terminal year was assumed equal to the geometric mean over the most recent 10 years. Population abundance in the terminal year was estimated for ages 2-5.

Diagnostics

Similar to last year, the population abundance estimates for the Base Case VPA show greater relative error in model fit (43%) and relative bias (9%) for age 2 while the relative error for ages 3-5 is lower (28-44%) and the bias is smaller (3-8%; Table 10). The population abundance estimates for the Major Change VPA show less relative error (28-33%) and less relative bias (3-6%) in model fit relative to the Base Case VPA (Table 11).

Survey calibration constants (q 's) for the Base Case VPA decline at the oldest age group (6+) for the DFO survey but continue to increase with increasing age for both NMFS surveys (Table 10). Survey calibration constants (q 's) for the Major Change VPA follow this pattern for the pre-1995 period, but all three level off or decline at older ages in the recent period (1995 to present) (Table 11). Comparing the q 's for each survey by the two time periods shows a large increase in catchability in the recent period, with some ages increasing more than five-fold and a nearly three-fold average increase (Fig. 20). There have been no changes in the survey design or operations that can explain such changes. These changes in q are considered to be aliasing unknown mechanisms for the sole purpose of producing a better fitting model.

The Base Case VPA continues to show a strong residual pattern in the DFO, NMFS Spring, and NMFS Fall surveys (Fig. 21). There is a large block of positive residuals (observed greater than predicted) over all ages from approximately 1996 to 2003 which is preceded by approximately a decade of mostly negative residuals in each of these surveys. The most recent years in the surveys have a mix of positive and negative residuals. The model is predicting an increase in abundance for all ages in recent years that is leveling off while the survey observations have a strong up then down pattern since 1995. The residual pattern for the Major Change VPA is much better than the Base Case VPA with more mixed positive and negative residuals, as expected due to splitting the time series in 1995 (Fig. 22). The average magnitude of residuals has also decreased compared to the Base Case VPA, as expected due to the addition of 18 parameters.

Retrospective analysis for the Base Case VPA indicates a strong tendency to underestimate fishing mortality on ages 4-5 and to overestimate spawning stock biomass (Fig. 23). In contrast, the Major Change VPA did not exhibit a consistent retrospective pattern, updates were both above and below previously estimated values (Fig. 24). The retrospective pattern observed in the Base Case VPA has resulted in decreases to the terminal year spawning stock biomass when updated, averaging a 41% decrease over the past five years (range: 24% to 59% decrease) with the most recent update exhibiting a 37% decrease. The Major Change VPA retrospective results have been both positive and negative over the past five years, averaging a 14% decrease (range: 47% decrease to 59% increase), with the most recent update exhibiting an 18% decrease.

Trends in age 3+ biomass from the Base Case VPA do not follow the same trend in recent years as seen in all three surveys (Figs. 13 and 25), and this model was rejected at the 2007 TRAC meeting as the basis for management advice. The Major Change VPA better reflects the recent trend observed in all three surveys (Figs. 13 and 25) and was recommended by the TRAC as the basis for management advice.

STOCK STATUS

Results from the Major Change VPA model formulation were used to evaluate the status of the stock in 2006 (Tables 12-13). The fishery weights at age, assumed to represent mid-year weights, were used to derive beginning of year weights at age (Table 14), and these were used to calculate beginning of year population biomass (Table 15). In the US, spawning stock biomass is the preferred metric for biomass and is computed assuming maturity at age and the proportion of mortality within a year that occurs prior to spawning ($p = 0.4167$).

Beginning of year population biomass (Ages 1+) declined from about 32,000 t in 1973 to a historic low of about 4,000 t in 1988, increased through the early 2000s and then declined to 7,093 mt in 2005 and increased to 7,788 mt at the beginning of 2006 (Table 15). Age 3+ (adult) biomass followed a similar trend, with a low of 2,221 mt in 1995, an increase to 11,370 mt in 2003, a decrease to 4,358 mt in 2006, and an increase to 6,232 mt at the beginning of 2007 (Table 15). Spawning stock biomass also followed a similar pattern, SSB in 2006 was estimated at 5,009 mt (Fig. 26).

Age 1 recruitment improved during the early 2000s compared to the period 1980 to the mid 1990s, but is now returning towards those levels, averaging 24 million age-1 fish during the past five years (Table 12; Fig. 26). Previous assessments had indicated the presence of some larger recruitment in the late 1990s as well, but their magnitudes have subsequently been estimated to be much smaller. The VPA estimates the 2005 year-class as strong (63 million age-1 fish in 2006), comparable to year classes in the 1970s and near the highest value in the time series.

Fishing mortality for fully recruited ages 4+ was close to or above 1.0 between 1973 and 1994, fluctuated between 0.58 and 0.95 during 1996-2003, increased in 2004 to 1.88, and then declined to 0.89 in 2006 (Table 13; Fig. 27, upper panel). Fishing mortality was well above the reference point of $F_{ref}=0.25$ for the entire time series, which agrees with assessment results from last year, but contrasts with the perception of being below F_{ref} since 1995 as estimated in pre-2005 assessments. The fully recruited (ages 4+) exploitation rate averaged 62% in both VPAs from 1973-1994, declined in 1995, spiked upwards dramatically in 2004 and in 2006 is estimated at 54%, which is well above the 20% exploitation equivalent to F_{ref} (Fig. 27, lower panel). Both the fishing mortality rate and exploitation rate were calculated for ages 4+. Due to the structure of the VPA, the F values for ages 4, 5, and 6+ are all the same. Thus, for these ages the unweighted average F will always be equivalent to the population abundance weighted average F in any year.

FISHERY REFERENCE POINTS

Yield per Recruit Reference Points

Although the yield per recruit analysis was not updated this year, an estimate of $F_{0.1}$ for ages 4+ was calculated from the past yield per recruit analysis of Neilson and Cadrin (1998; $F_{0.1}$ for ages 4+ = 0.25; exploitation rate=20.0%). This is the same value as the F_{MSY} proxy of $F_{40\%MSP}$ used for US management (NEFSC 2002).

Stock and Recruitment

There is evidence of reduced recruitment at low levels (below 5,000 mt) of spawning stock biomass (Fig. 28). Based on the spawning stock biomass and recruitment relationship observed in a previous stock assessment, the B_{MSY} level of 58,800 t of spawning stock biomass was set as the rebuilding goal in the US for this stock (NEFSC 2002). Current levels of SSB are considerably lower than the rebuilding goal (9%).

OUTLOOK

The outlook is typically provided in terms of the possible consequences for alternative catch quotas in 2008 with respect to the harvest reference points. Uncertainty about stock size generates uncertainty in forecast results. It is considered that in this assessment these uncertainties, particularly those associated with the changes in survey catchabilities, are more problematic than in other assessments. As such, the standard risk plots do not capture the extent of uncertainty of the consequences for various catch levels. A sensitivity analysis illustrates the dependence of the projected 2008 catch on the magnitude of the 2005 year-class.

Yield was projected deterministically using 2007 beginning of year population abundance estimates, assuming a 2007 catch equal to the 1,250 mt quota. Recruitment in 2007-2009 was set equal to 20.5 million age-1 fish (geometric mean of the previous ten years), and partial recruitment to the fishery was estimated as the average of the previous three years. Projected total Canada/US yield at $F_{ref} = 0.25$ in 2008 would be 3,531 mt (Table 16). If fished at F_{ref} in 2008, the total biomass is projected to increase from 25,475 mt in 2008 to 28,951 mt at the beginning of 2009. The 2007 quota of 1,250 t causes projected fully recruited F to be below F_{ref} in 2007 ($F_{2007} = 0.20$), due mainly to the 2005 year-class entering the fishery.

The 2005 year-class accounts for 59% of the 2008 catch, 73% of the 2008 age 3+ biomass, and 60% of the 2009 age 3+ biomass. To demonstrate the sensitivity of these projections to the strength of the 2005 year-class, deterministic projections were repeated with the 2007 age 2 value (the 2005 year-class) replaced by the average during 1997-2006 (14.8 million fish at age 2). Catching the 2007 TAC of 1,250 mt and fishing at F_{ref} in 2008 generates a combined Canada/USA catch of 1,989 mt (44% lower than the default projections). The age 3+ biomasses in 2008 and 2009 are 10,018 mt (53% lower than the default) and 13,940 mt (44% lower than the default), respectively. The 2005 year-class now only accounts for 30% of the 2008 catch, 44% of the 2008 age 3+ biomass and 31% of the 2009 age 3+ biomass. This sensitivity analysis is an extreme example because the average age 2 population abundance during 1997-2006 of 14.8 million fish, is well below the lower 80% confidence interval estimated from bootstrapping (34.6 million) and the point estimate (51.5 million) for the 2005 year class at age 2 in 2007. However, in the past, some year-classes that were estimated as strong were later found to be average when the cohort was observed for more years. If a 2008 TAC of 3,531 mt is caught, and the 2005 year-class is only average, the resulting fishing mortality rate would be about twice F_{ref} .

Age structure, fish growth, and spatial distribution reflect stock productivity. The current age structure indicates that very little rebuilding of ages 5 and older has occurred and that the population is still dominated by younger ages 1 through 4 (Fig. 29). Far fewer older fish (6+) are estimated in the VPA in comparison with the population at equilibrium, which is inconsistent with the perception of recent low exploitation. The spatial distribution patterns from the NMFS and DFO surveys suggest a concentration in stratum 16, while the inability of Canadian fishermen to find commercial concentrations of yellowtail the past three years suggests a westward shift in distribution. Truncated age structure in the surveys and change in distribution indicate current productivity may be limited relative to historical levels.

MANAGEMENT CONSIDERATIONS

This assessment is hampered by inconsistencies between the magnitude of the catch, age structure of the catch and the age-specific indices of abundance. Although the catch of old fish has increased in recent years, it is still less than would be expected given the increases seen in the age-specific indices of abundance. The noisy character of the indices cause difficulty in tuning age structured models.

Both VPA formulations have difficulties with interpretation (see benchmark report for full details; TRAC 2005). The Base Case VPA has a strong pattern in residuals and a strong retrospective pattern. The Major Change VPA adds parameters to decrease these patterns in residuals and the retrospective, but the mechanism for the changes in survey catchability are not easily explained. These changes in survey catchability are most appropriately thought of as an aliasing of an unknown mechanism that produces a better fitting model. However, the closer match of the Major Change VPA to the recent trends seen in all three surveys made it the choice for management decisions at the TRAC meeting (O'Boyle and O'Brien, 2007).

Assessments exhibiting retrospective patterns have difficulty making accurate forecasts. This can be observed for Georges Bank yellowtail flounder by comparing the 2006 catch at age from three assessments (Fig. 30). The 2005 assessment made a two year projection of the 2006 catch at age, while the 2006 assessment made a one year projection of the 2006 catch at age, and the 2007 assessment derived the 2006 catch at age from the observed catch. The 2005 assessment projected the 2006 catch at age from the estimated 2004 population abundance assuming the 2005 catch would be 6,000 mt and $F_{2006} = 0.25$. The 2006 assessment projected the 2006 catch at age from the estimated 2005 population abundance assuming the 2006 catch would be 3,000 mt and projected the associated F_{2006} to be 0.30 (Base Case) or 0.83 (Major Change). The 2007 assessment derived the 2006 catch at age from the actual catch of 2,206 mt and estimated F_{2006} to be 0.39 (Base Case) or 0.89 (Major Change). The Base Case shows a progressive increase in F from 0.25, to 0.30 to 0.39 for the 2005-2007 assessments, while the Major Change VPA shows a larger initial change from 0.25 to 0.83 and then a small change to 0.89 for the 2005-2007 assessments, even though the projected catch was much higher in 2005 than actually realized. The distributions at age change more for the Base Case than the Major Change, with the Base Case projecting large numbers of age 4 and 5 fish in the 2005 and 2006 assessments that did not materialize. This highlights the difficulties of assessing this resource because of a strong retrospective pattern of unknown source, truncated age structure, and reliance on incoming year-classes. The current model, while an improvement over the Base Case model, should be used with these uncertainties in mind.

ACKNOWLEDGMENTS

Canadian port sampling was provided by Gilbert Donaldson and Emilia Williams. Many people in the Woods Hole lab assisted in the compilation of the US data. We thank Steve Cadrin and Kurtis Trzcinski for their thorough reviews of an earlier draft of this document.

Table 2. Derivation of discards of yellowtail flounder in 2006 by US trawl fishery, US scallop dredge fishery, and Canadian scallop dredge fishery using observer data. The US trawl discards are estimated based on the observed ratio of discarded yellowtail to kept yellowtail. The US dredge discards are estimated based on the observed ratio of discarded yellowtail to kept scallops. The Canadian dredge discards are estimated based on the observed ratio of yellowtail discards per hour fished, using a three month moving window for the d:e values. "N trips" denotes the number of observed trips for each cell. Percentages are for landings, discards, or effort by period for each sector separately.

US Trawl

Period	YT Landings (mt)		d:k ratio	YT Discards (mt)		N trips
Half 1	786.9	64%	0.0440	34.6	33%	154

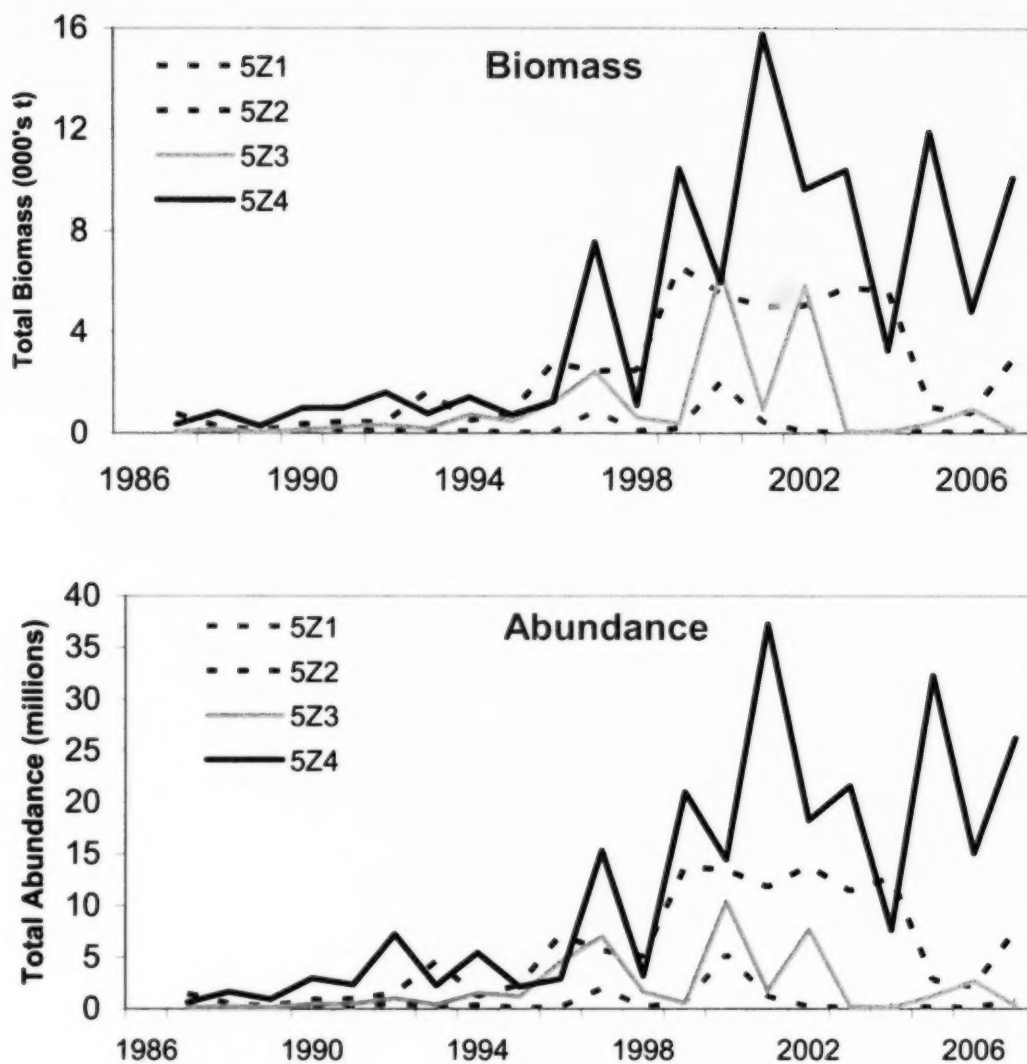

Figure 14. DFO spring survey estimates of total biomass (top panel) and total number (bottom panel) by stratum area for yellowtail flounder on Georges Bank, 1987-2007.

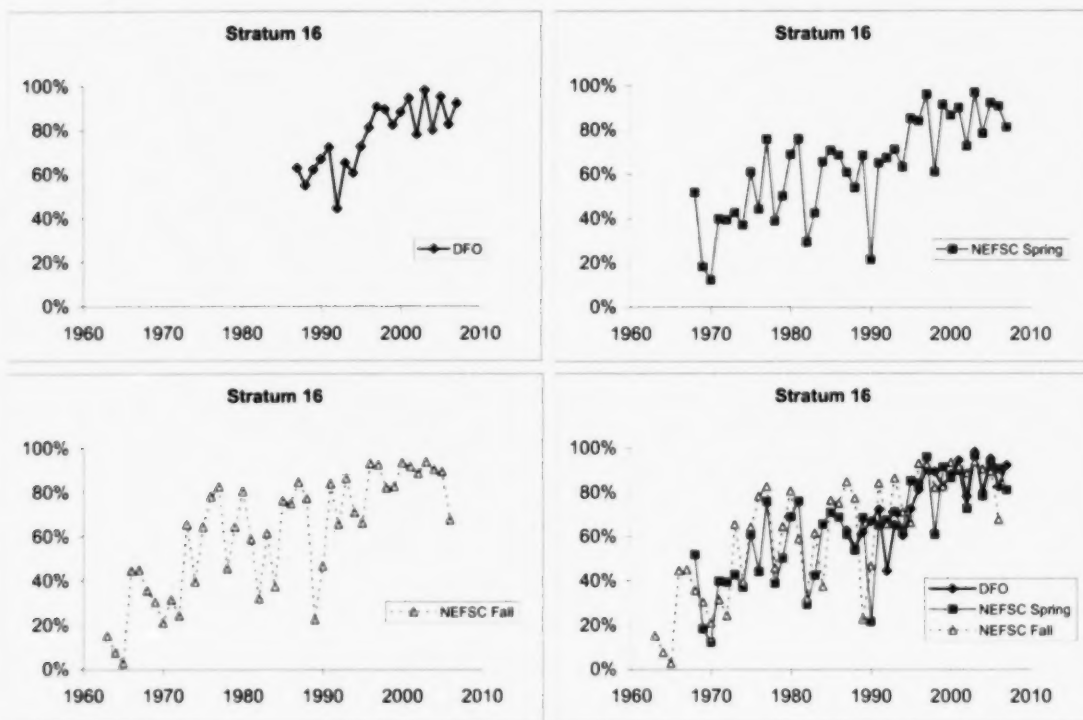

Figure 15. Proportion of survey biomass for yellowtail flounder on Georges Bank found in stratum 16 for DFO spring, NMFS spring, and NMFS fall surveys.

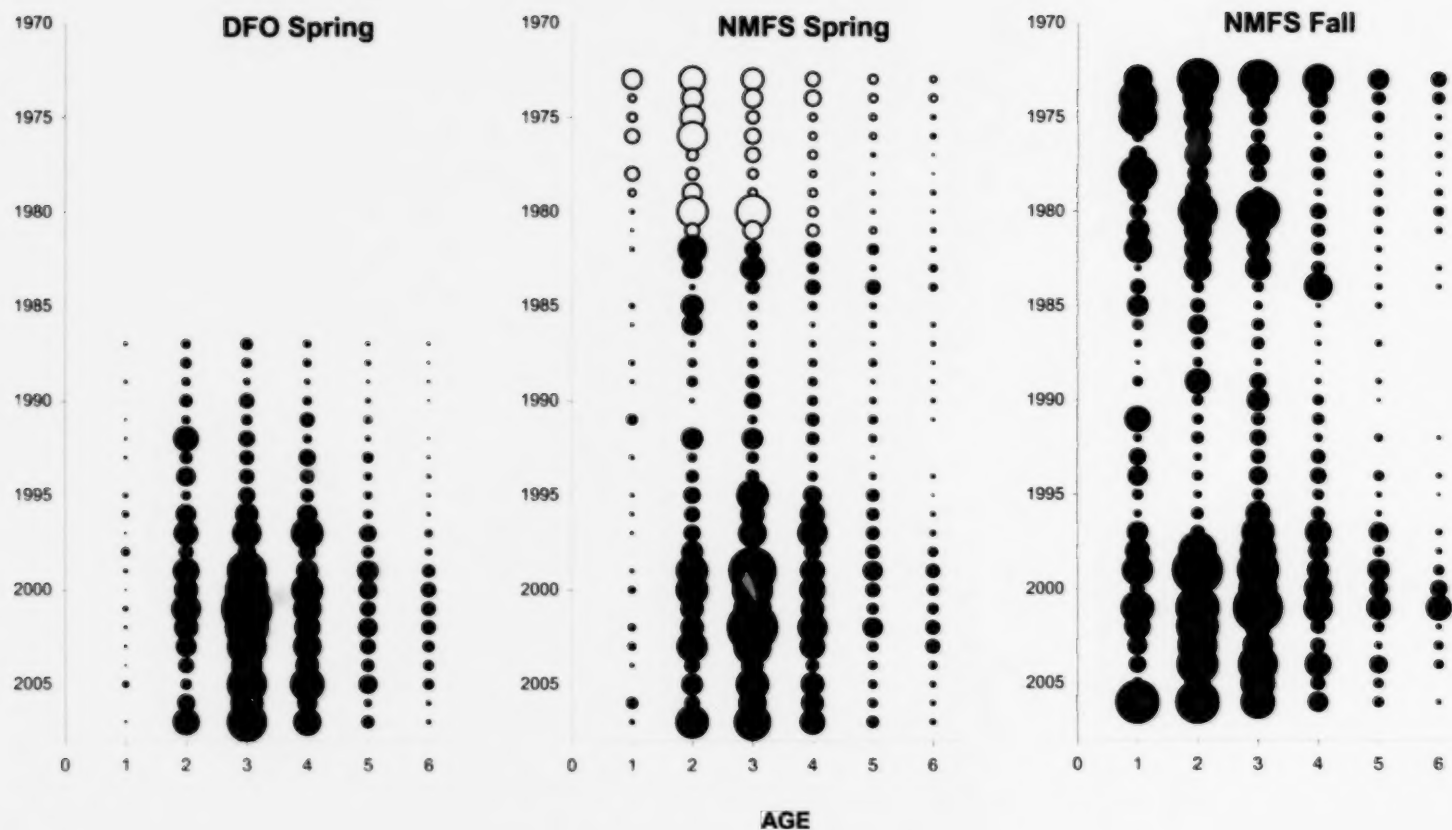

Figure 16. Age specific indices of abundance for the DFO spring (1987-2007), NMFS spring (1968-2007), and NMFS fall (1963-2006) surveys (bubble is proportional to the magnitude). The yellow symbols in the NMFS spring series denote the period when the Yankee 41 net was used (1973-1981). Age 6 denotes ages 6 and older. Refer to Tables 6, 7, and 8 for the specific values of the indices.

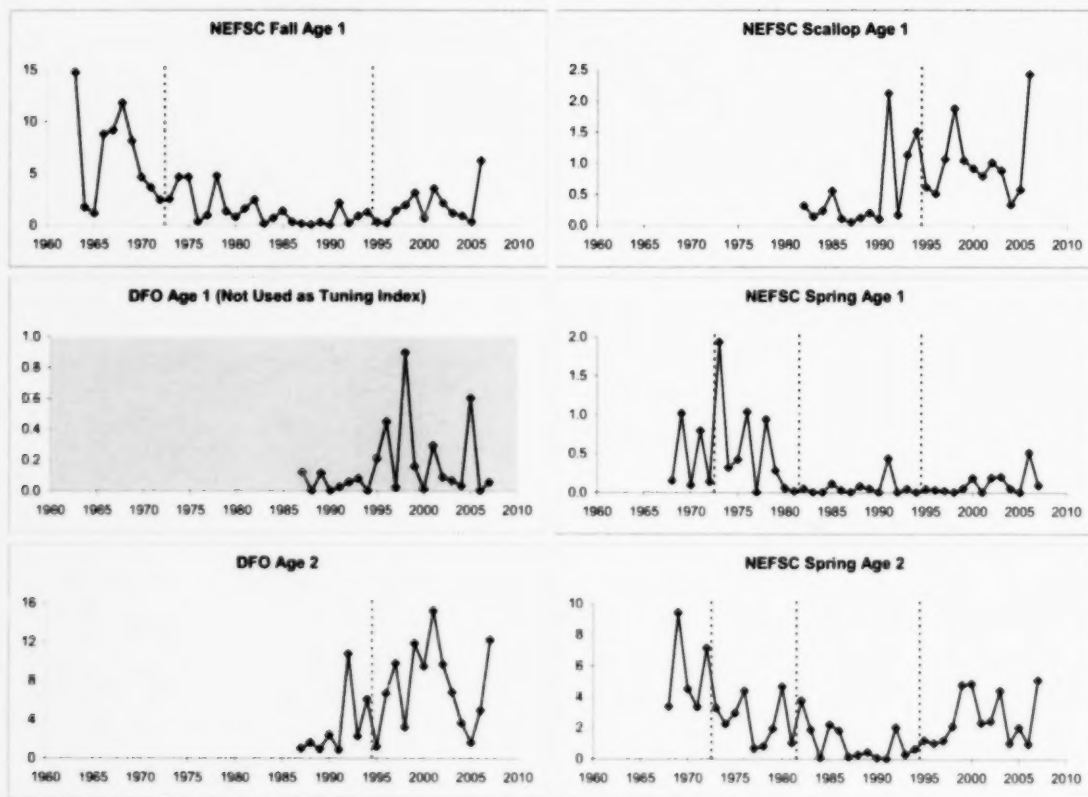

Figure 17. Survey indications of a strong 2005 year-class (denoted by red symbol; age-1 in 2006, age-2 in 2007). Vertical dashed lines indicate start of VPA time series (1973), switch from Yankee 41 to Yankee 36 net in Spring Survey (1982), and split of survey time series in Major Change VPA (1995). Refer to Tables 6-9 for the specific values of the indices.

Figure 18. Trends in relative fishing mortality (catch biomass/survey biomass), standardized to the mean for 1987-2005.

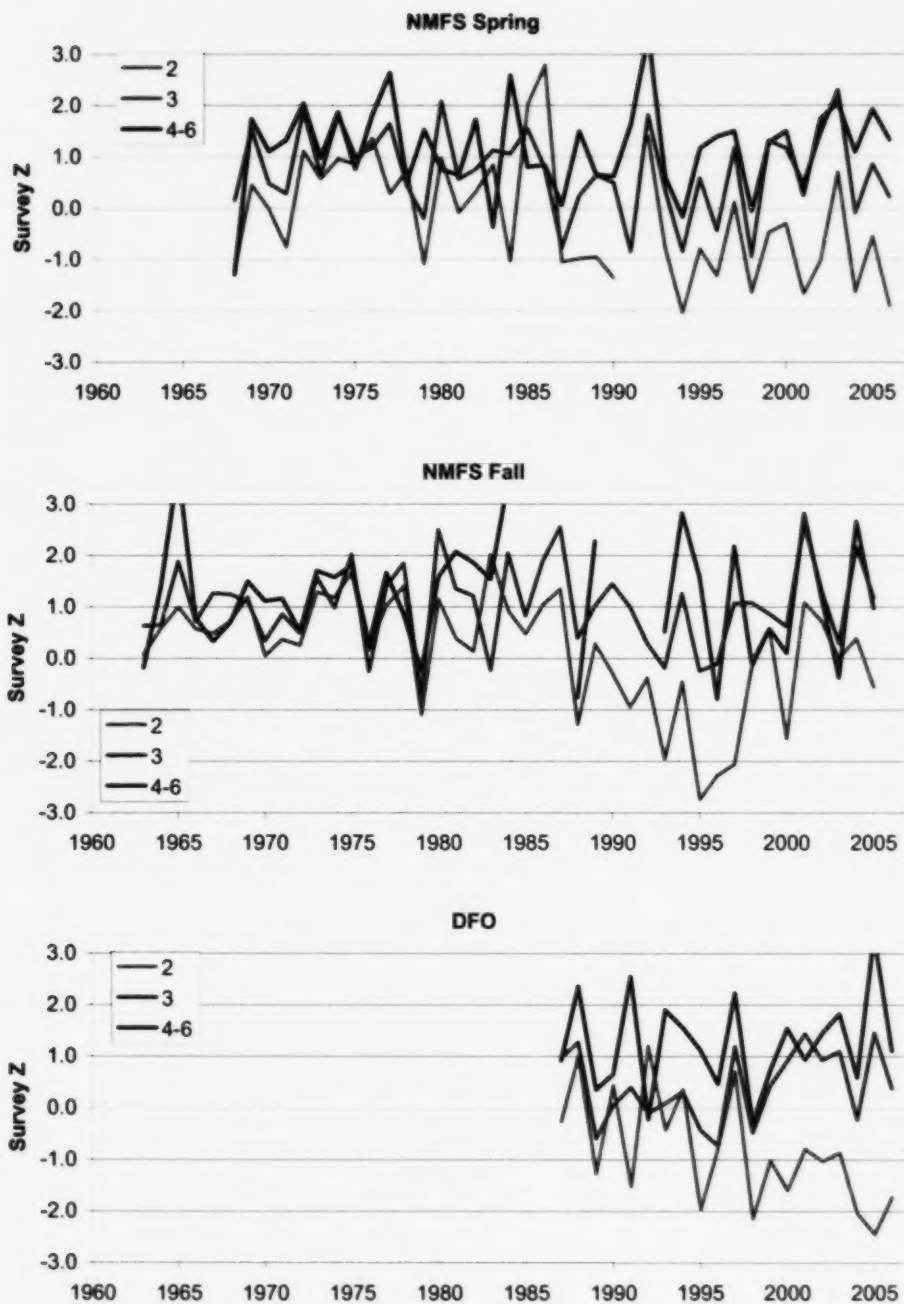

Figure 19. Trends in total mortality (Z) for ages 2, 3, and 4-6 from DFO, NMFS Spring and NMFS Fall bottom trawl surveys.

Figure 20. Catchability coefficients (q) from the Major Change VPA.

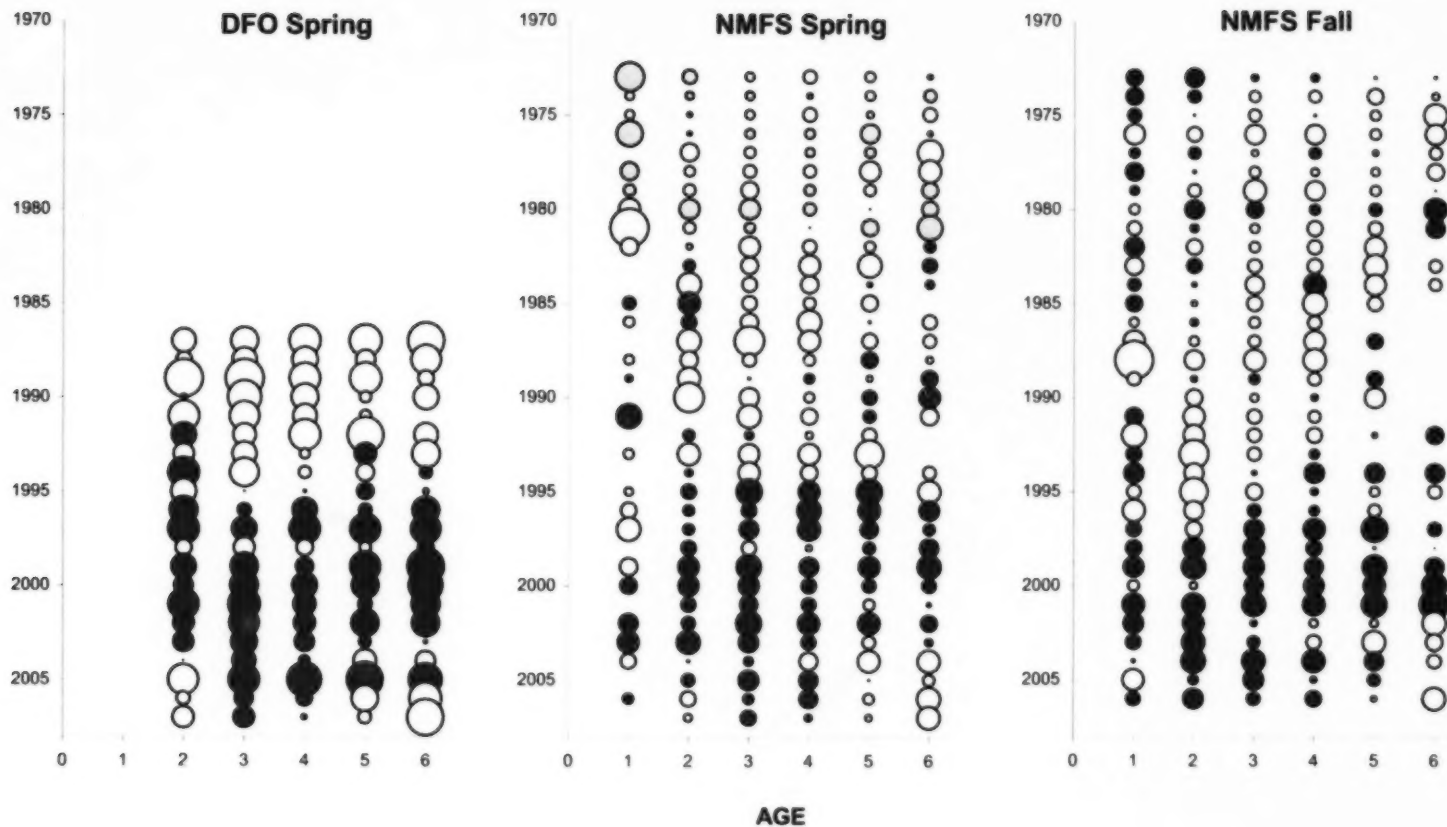

Figure 21. Age by age residuals from the Base Case VPA model formulation for \ln abundance index minus \ln population numbers, Georges Bank yellowtail flounder (bubble size is proportional to magnitude). The grey shaded symbols in the NMFS spring series denote the period when the Yankee 41 net was used. The open symbols denote negative residuals, and filled symbols denote positive residuals.

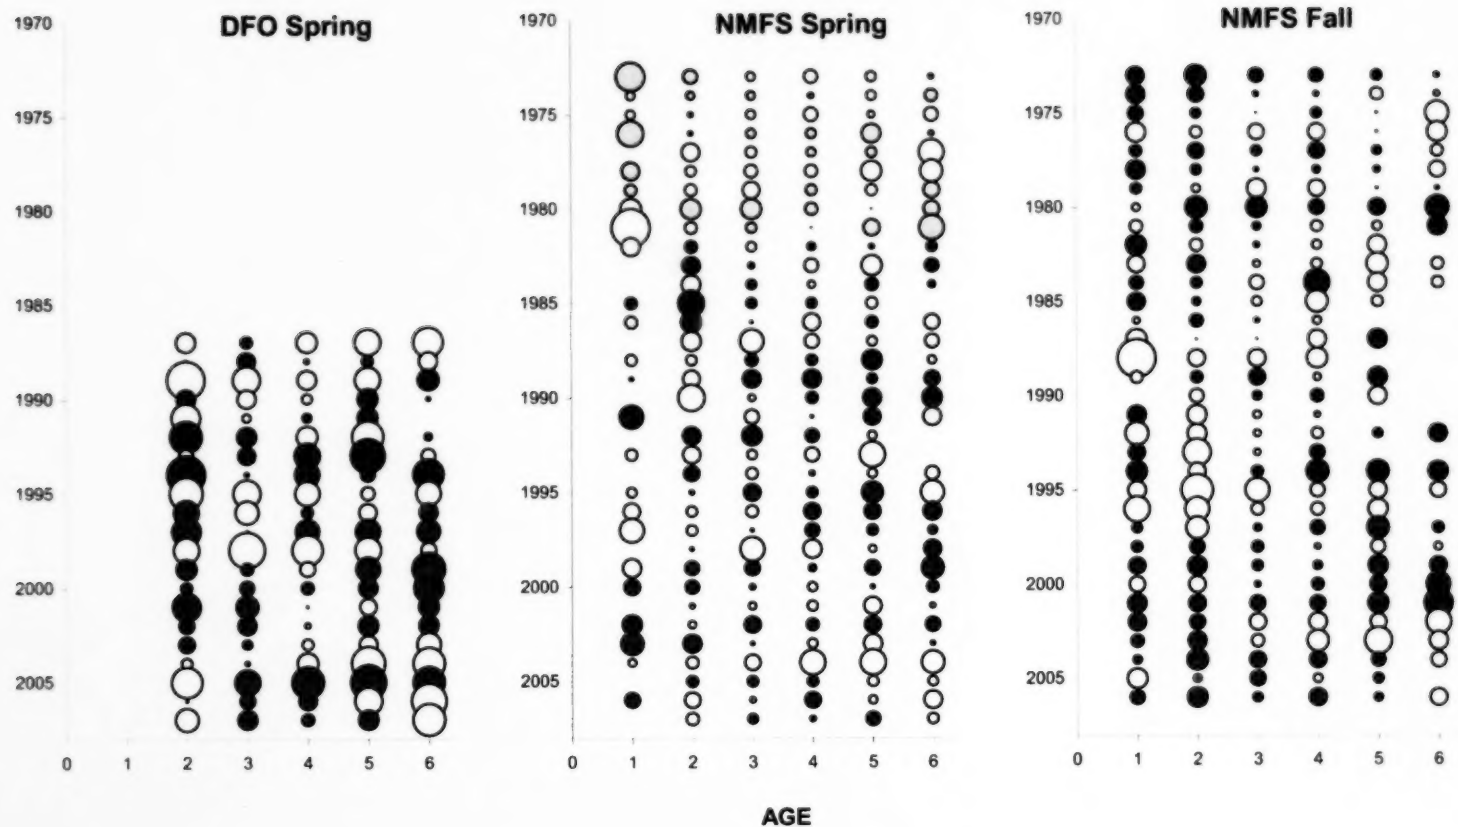

Figure 22. Age by age residuals from the Major Change VPA formulation for \ln abundance index minus \ln population numbers, Georges Bank yellowtail flounder (bubble size is proportional to magnitude). The different colors denote separate series. The open symbols denote negative residuals, and filled symbols denote positive residuals.

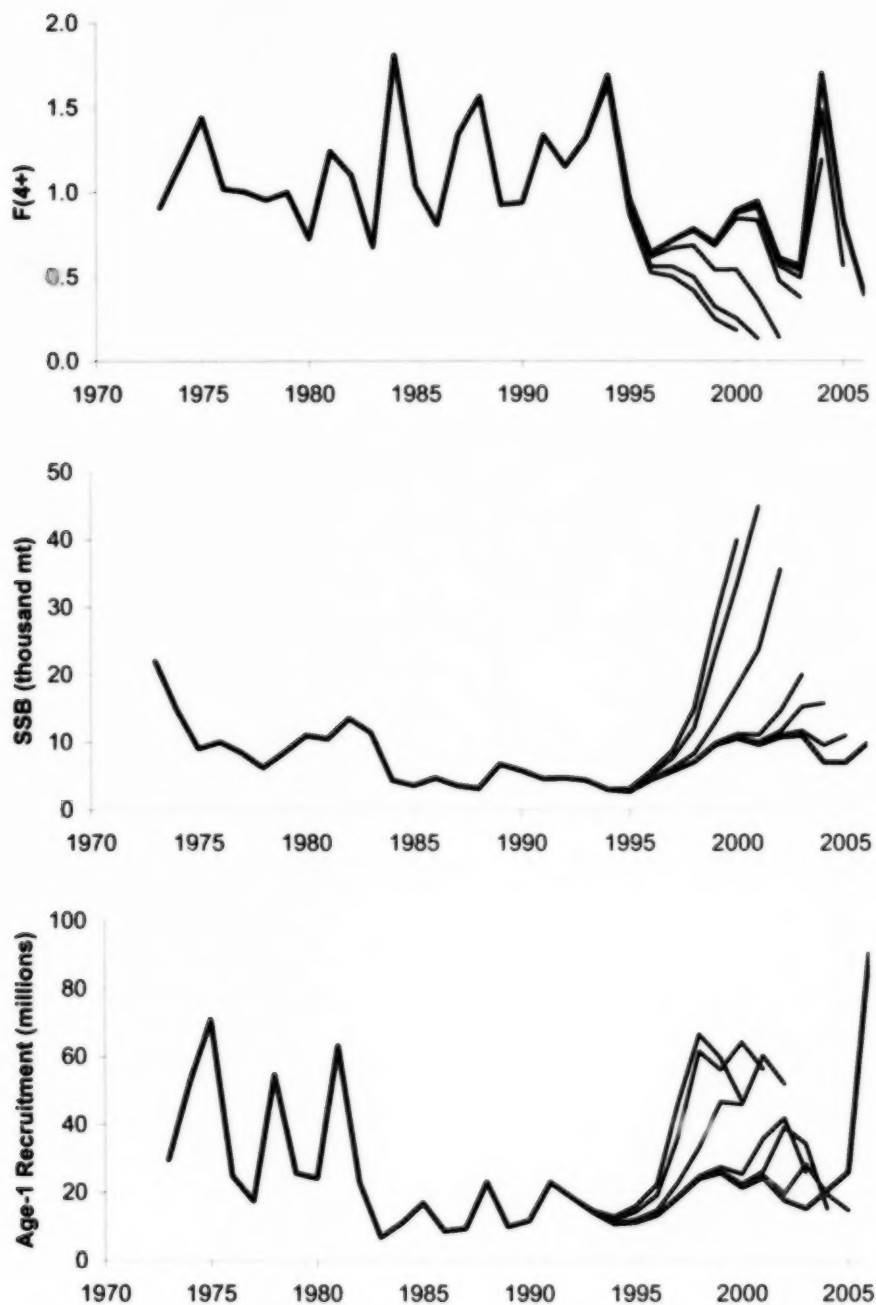

Figure 23. Retrospective analysis of Georges Bank yellowtail flounder from the Base Case VPA for age 4+ fishing mortality (top panel), spawning stock biomass (middle panel) and age 1 recruits (lower panel).

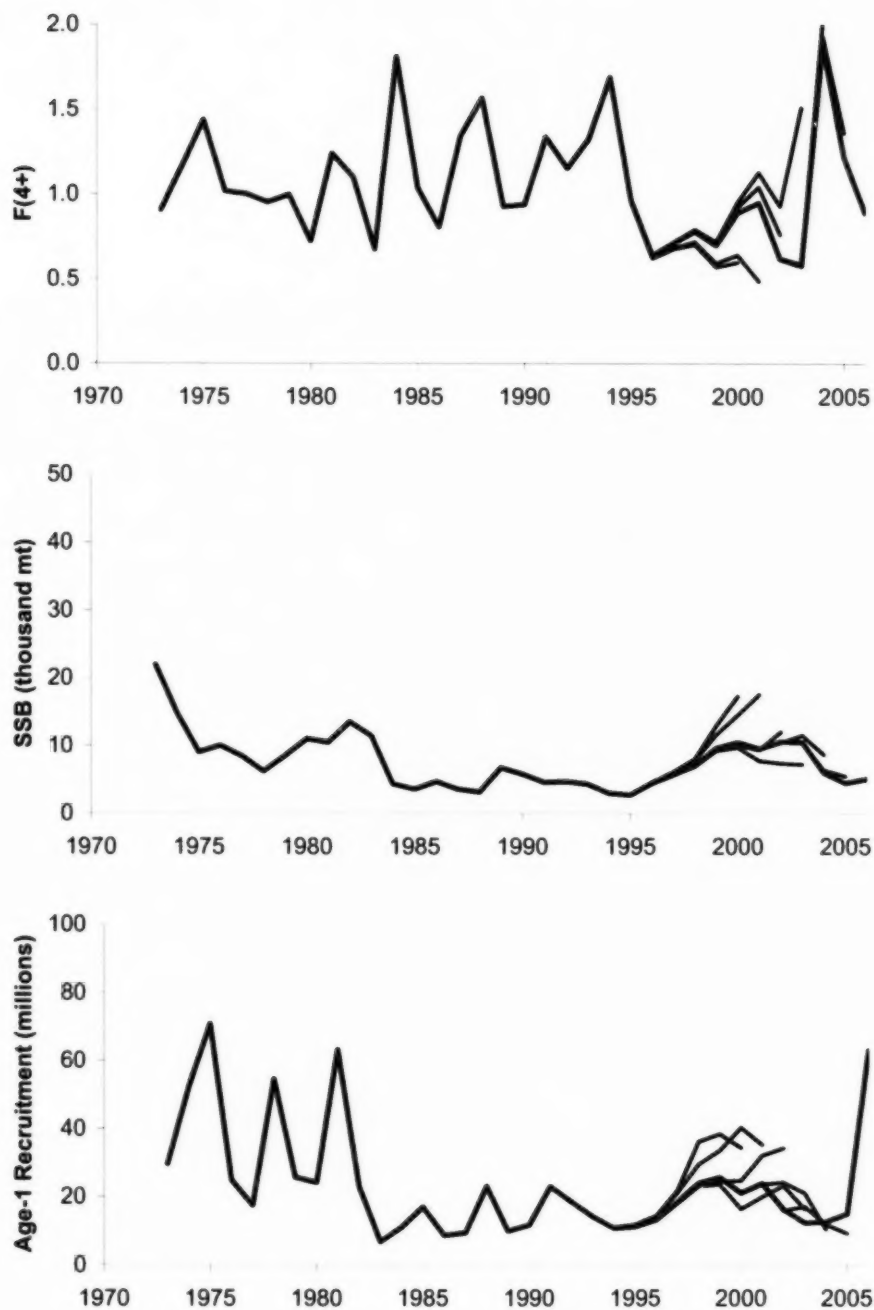

Figure 24. Retrospective analysis of Georges Bank yellowtail flounder from the Major Change VPA for age 4+ fishing mortality (top panel), spawning stock biomass (middle panel) and age 1 recruits (lower panel).

Figure 25. Trends in age 3+ biomass for Georges Bank yellowtail flounder as indicated from the Base Case VPA and Major Change VPA.

Figure 26. Trends in and spawning stock biomass and age 1 recruits for Georges Bank yellowtail flounder as indicated from the Base Case VPA and Major Change VPA.

Figure 27. Trends in fully recruited (age 4+) fishing mortality (upper panel) and exploitation rate (lower panel) for Georges Bank yellowtail flounder as indicated from the Base Case VPA and Major Change VPA.

Figure 28. Spawning stock biomass and age 1 recruitment relationship for Georges Bank yellowtail flounder from the Major Change VPA formulation. Strong year-classes of recruitment are noted by the year of SSB and year-class for recruitment. The spawning stock biomass for 2006 (red square) is also shown on the x-axis.

Figure 29. Proportions at age for the Georges Bank yellowtail flounder population in 2006, for the average of 1973-2005, and when the population is at equilibrium at the Fref of 0.25, based on results from the Major Change VPA. The lower panel shows the same information but without inclusion of age 1 values, which were high in 2006.

Figure 30. Comparison of the projected and observed 2006 catch at age from the two models and three assessments. The 2005 assessment projected the 2006 catch at age from the estimated 2004 population abundance assuming the 2005 catch would be 6,000 mt and $F_{2006} = 0.25$. The 2006 assessment projected the 2006 catch at age from the estimated 2005 population abundance assuming the 2006 catch would be 3,000 mt and projected the associated F_{2006} to be 0.30 (Base Case) or 0.83 (Major Change). The 2007 assessment derived the 2006 catch at age from the actual catch of 2,206 mt and estimated F_{2006} to be 0.39 (Base Case) or 0.89 (Major Change).

Appendix

Domain Estimation for Converting DFO Survey to NEFSC Strata

Special thanks to Stephen Smith (DFO) for this work

The DFO and NEFSC surveys are both stratified random designs, but use different stratifications. In order to compare the DFO survey to the NEFSC survey in terms of the concentration of yellowtail flounder on Georges Bank, a conversion between the stratifications must be made. This conversion is known as domain estimation (Särndal et al. 1992). The average catch by the DFO survey in the NEFSC strata cannot be used directly because the tows were not selected randomly from within the NEFSC strata, but rather from within the DFO strata. Domain estimation accounts for the original sampling scheme while computing the mean catch per new stratum using the following process. Define y_k as the k th observation that falls into DFO stratum h and NEFSC domain d , where n_{dh} is the sample size for this combination and H is the total number of DFO strata. The sample size (number of tows) for DFO stratum h is n_h while N_h is the total number of possible samples that could be taken from DFO stratum h . Hence the probability of choosing observation y_k is n_h/N_h in NEFSC domain d . The mean for NEFSC domain d is estimated as

$$\hat{\bar{y}}_d = \sum_{h=1}^H \frac{N_h}{n_h} \sum_{k=1}^{n_{dh}} y_k \bigg/ \sum_{h=1}^H \frac{N_h}{n_h} n_{dh} .$$

An example of domain estimation for the converting the DFO survey to NEFSC strata is provided in Fig A1. The raw survey data are in the top two boxes on the left side, the sum of yellowtail flounder caught and the number of tows that occurred in the intersections of the DFO and NEFSC strata. For example, the DFO survey randomly allocated 10 tows in stratum 5Z1, which happened to occur in NEFSC strata 1160, 1170, and 1210. The box below the raw data contains the total number of tows by DFO strata (n_h), the total number of possible tows (N_h) and the ratio of these values. The boxes on the right show the partial calculations for the estimated means, while the box at the bottom left contains the final estimates.

Sum of Yellowtail Caught (kg)				
NEFSC Strata	DFO Strata			
	5Z1	5Z2	5Z3	5Z4
